Abstract

Financial innovation refers both to technological advances which facilitate access to information, trading and means of payment. The demand for money is very crucial in the conduct and determination of the effectiveness of monetary policy. This study attempts to analyse whether financial innovations that occurred in Nigeria after the Structural Adjustment Programme of 1986 has affected the demand for money in Nigeria using the Engle and Granger Two-Step Cointegration technique. Though the study revealed that demand for money conforms to the theory that income is positively related to the demand for cash balances and interest rate has an inverse relationship with the demand for real cash balances, it was also discovered that the financial innovations introduced into the financial system have not significantly affected the demand for money in Nigeria. Based on the results obtained, a policy of attracting more participants (non-government) and private sector funds to the money market is necessary as this will deepen the market and make the market more dynamic and amenable to monetary policy. Therefore, the study concludes that financial innovation has had no significant impact on the demand for money in Nigeria and the SAP era financial liberalization policies have had no indirect impact on the demand for money as well.

1. Introduction and Problem Statement

The concept of financial innovation is not an entirely new phenomenon in economics but its pace over the last two decades of the twentieth century has thrown up new challenges to perhaps one of economics most hotly debated topics: the demand for money. The empirical study of the demand for money is one of the most popular subjects in applied econometrics (Melnick, 1995). The search for a stable demand for money has been a very contentious issue since the great intellectual debates between Keynesians and Monetarists of the 1960s and 1970s, as no demand for money model set forth by any of these two schools as well as their contemporaries has withstood the test of time. The instability of the demand for money in the 1970s and in the 1980s has been attributed primarily to changes in the performance of financial markets in the area of new financial products arising out of financial innovations.

Financial innovation is becoming increasingly important in the 21st century as it poses a serious problem for monetary policy, as with new financial products the ability of monetary policy to be effective diminishes, as it changes one variable vital for effective monetary policy; the demand for money. Financial innovation refers both to technological advances which facilitate access to information, trading and means of payment, and to the emergence of new financial instruments and services, new forms of organization and more developed and complete financial markets (Solans, 2003). With new financial products, contractionary monetary policy for instance, targeted at reducing excess liquidity as economic agents can easily move money from less liquid holdings to more liquid packages being offered by financial intermediaries. In the process, undermining monetary policy, the reverse occurs vice-versa. In effect financial Innovation has also raised serious problems in the definition and measurement of money. This study seeks to replicate empirical works carried out in the Western world in Nigeria to see if financial innovation has had significant effects in altering the demand for money in Nigeria.

There is and has always been considerable disagreement among economists over what determines the levels and rates of growth of output, prices and employment. The appropriate tool for macro-economic stabilization depends on the underlying theory in use. Keynesians would go for fiscal policy while monetarists would clamour for monetary policy. Monetary policy refers to the use of interest rates, money supply and credit availability to achieve macro-economic objectives. The use of monetary policy as a tool for macro-economic stabilization depends largely on the behaviour of the demand for money or real cash balances in the hands of economic agents. This brings in the demand for money function which expresses a mathematical relationship between the quantity of money demanded and its various determinants; interest rate, income, price level, credit availability, frequency of payments etc. The stability of these relationships (elasticities) is vital for in determining the appropriateness and effectiveness of the tools or instruments of monetary policy.

The year 1973 is a watershed in the history of the various models and specifications put forth as regards the demand for money as Stephen Goldfeld published his analysis of post-World War II quarterly data on the demand for money using M_1 definition of money (i.e. currency in circulation + demand deposits) and found that the real income elasticity of demand for real M_1 balance was positive but less than one. The interest rate elasticity of demand is negative and the demand for nominal cash balances is proportional to the price level. Hence the demand for money is the demand for real balances and no money illusion exists. (Miller & Pulsinelli, 1986)

However, in recent times the instability of the previously stable money demand for money function has thrown up new studies at its various determinants and several other fronts have been explored by economists and econometricians alike. One of these fronts is financial innovation which has blurred the distinction between M_1 and other assets. It has blurred the various definitions of money – M_1 , M_2 , M_3 etc (*ibid*).

In Nigeria, it has begun to hit home with the recent recapitalization of the banking sector, with the banks now bringing in new financial products that have combinations of savings features, higher interest earnings, easy withdrawals and transfers, with increasingly close substitutes for money being introduced by the day, good news for customers but a hellish nightmare for monetary authorities.

The main problem with the stability of the demand for money began with one man's work in 1973, American professor; Stephen Goldfeld. Prior to 1973, the evidence that had accumulated from the large body of research done over the post – world war period was interpreted as showing that a stable demand function for money did, in fact, exist. In 1973, Stephen M. Goldfeld computed a demand for money function using quarterly postwar data up to 1973. Although Goldfeld's results differed in several important ways from those of the earlier literature, which were based mainly on annual data, his preferred specification became the standard formulation. Goldfeld's findings held that the quarterly demand function for money was most stable when:

- (i) A narrow transactions definition of money was used.
- (ii) A short-term market rate of interest like the Treasury bill or commercial paper rate was used and when the rate on savings deposits was included.
- (iii) Measured income (real GNP) was used rather than permanent income or wealth.
- (iv) Lagged money was included to allow for incomplete adjustment in the short run.

But starting in 1974, forecasts from Goldfeld's equation began to seriously over predict real money balances. When the equation was re-estimated with data including post-1973 data, The coefficient on the lagged dependent variable became very large (implying implausibly long adjustment lags) and sometimes it was having values greater than unity (implying money demand is dynamically unstable). Soon, the demand for money function had become "unstable" in the sense that it had become more difficult to predict without serious accuracy errors.

This problem of estimating a stable money demand function as stated earlier has thrown up several lines of research. A line of inquiry sought to look at the pre-1973 agenda of empirical issues that focused on interest rate and inflation. Another line of investigations have suggested that the trouble is linked to changes in the financial market (e.g. Garcia and Pak 1979, Goldfeld 1976, and Simpson and Porter 1980). It is argued that financial innovations have led to deterioration in the marginal relationship between real money balances and interest rates. Economic literature stating that financial innovations affect the link between interest rates and money demand are not entirely new (Judd and Scadding, 1982). Infact, this is the building block of the theories of Gurley and Shaw (1960) They posited that the definition of money should include all other assets which can serve as close substitutes for money, then by attaching respective weights to this assets depending on the level of their substitutability, Gurley and Shaw hypothesized a wide proliferation of money substitutes which increased the interest elasticity of money demand.

The paper has five sections, each dealing with the different aspects of the study. Section one, which is this section is the introductory section. Section two presents a review of relevant literature, while section three discusses the theoretical framework and model specification of the study. Section four focuses on model estimation and analysis of the regression result and fifth section concludes the paper with relevant policy proposals.

1.1. Objectives

The broad objective of this study is to examine the role of financial innovation on money demand in Nigeria. The specific objectives of this study include:

- 1) To examine the degree of the relationship between financial innovation and the money demand in the Nigerian economy.
- 2) To see how this relationship affects the effectiveness of monetary policies in Nigeria.
- 3) To make policy recommendations based on the findings of the study.

1.2. Justification

This study is of utmost importance as it looks at several reasons accounting for the instability of the demand for money which is very vital in determining the effectiveness of monetary policy. These are as follows;

- 1) It is important to know if money demand function is unstable as a result of financial innovation. Knowing this is vital to the relationship between interest rates and aggregate expenditure as this is important for choosing instruments for conducting monetary policy. If the demand for money is significantly affected, then the case for conducting macro-economic stabilization by regulating the growth of the money supply and interest rate changes may be seriously threatened. As such this research project will be of importance to monetary policy makers (Central Bank of Nigeria)

1.3. Research Hypothesis

In testing the relationship between financial innovation and the demand for money two hypotheses will be drawn as follows:

- a) The relationship between financial innovation and the demand for money;
 - H_0 : Financial Innovation has no impact on the Demand for Money.
 - H_1 : Financial Innovation has an impact on the Demand for Money.
- b) The relationship between SAP era financial sector liberalization and the demand for money;
 - H_0 : SAP era Financial Sector Liberalization policies have had no impact on the Demand for Money.
 - H_1 : SAP era Financial Sector Liberalization policies have had an impact on the Demand for Money.

2. Review of Relevant Literature

Over the last two decades, an enormous body of literature has documented the continuing instability of standard econometric money demand specifications and attributed the instability to innovation in the private financial sector, Ireland (1995). The question of whether the demand for money function is stable is one of the most important recurring issues in the theory and application of macroeconomic policy. What is being sought in a stable demand function is a set of necessary conditions for money to exert a predictable influence on the economy so that the central bank's control of the money supply can be a useful instrument of economic i.e monetary policy.

What then is the demand for money? The demand for money can be defined as the desire to hold money in liquid form rather than other forms of wealth such as stocks, bonds, etc. it often stems from three main motives, which are; transactionary, precautionary and speculative which are influenced by several factors; levels of income and wealth, rates of interest, expectations of economic agents and institutional features of an economy, (Bannock et al 1998). Put differently, it is the desire to hold cash or liquid assets rather than the equivalent in demand deposits. It is also known as liquidity preference.

The conventional money demand equation has been one of the most widely studied relationships in macroeconomics. It generally features real money balances being affected by contemporaneous levels of real income as a proxy for transactions, and a nominal interest rate that describes the opportunity cost of holding money. The variables that enter the demand function for money, and the definition of the quantity of money appropriate for the demand function, have received substantial attention in economic literature.

First, there is the question of the constraint that is imposed on money balances, whether the appropriate constraint is a measure of wealth or income, or some combination of the two. The second issue in most literature has centered on the importance of interest rates and price changes as arguments (independent variables) in the demand function. The third issue is the question of the definition of

money balances. Is a more stable demand function obtained if money is defined inclusive or exclusive of time and/or savings deposits, and perhaps other assets that have value fixed in money terms? i.e. either M_1 or M_2 .

A rich tradition exists on the estimation of money demand in the United States than in any other country. Going by economic literature, the differences in the specification of the variables in the money demand function have produced important differences in implications or results. Tobin (1956) and Baumol (1952) separately considered the transactionary demand for money as a problem in capital theory and each obtained a demand function for cash balances which depends on costs and yields. Both Baumol and Tobin deduced from their models that there are economies of scale in holding transaction balances. An income or wealth elasticity less than unity would confirm this implication. Friedman's empirical findings however suggest that money is a "luxury" and that the relevant elasticity is in the neighborhood of 1.8. (Friedman 1959). However going by empirical literature, most Economists seem to accept Friedman's empirical result in preference to those of Baumol (1952) and Tobin (1956), though there seems to be some debate over the specification of the variables in Friedman's money demand function. Specifically, Friedman's use of per capita permanent income combines wealth, interest rates, population, and lagged income into a single variable which combines and masquerades their separate effects.

Tobin (1958) accorded the rates of return on financial and non-financial assets an important role in his theory of asset choice. Friedman's essay on the quantity theory stresses a view of the quantity theory as a theory of the demand for money. He uses bond and equity yields as direct arguments in the demand function. But his empirical findings suggest the importance of per capita permanent income and exclude interest rates as direct arguments of the function or assign them a role of second order of importance. Bronfenbrenner and Mayer (1960) estimated the separate effects of wealth and interest rates along with income and lagged money balances. Their results show that interest rate, income, and lagged money balances are statistically significant by the usual tests, but the wealth variable is non-significant.

Another issue quite common in literature is the definition of money is itself which still remains an open question. Gurley and Shaw (1960) suggested that monetary theory should be concerned with a concept broader than the liabilities of commercial banks. Friedman's empirical work is based on a concept of money that includes the time deposit liabilities of commercial banks while Latane (1954), Bronfenbrenner and Mayer (1960) and others have been chiefly concerned with money defined as the sum of demand deposits and currency.

In terms of econometric work, Courchene and Shapiro (1964) identified certain dynamic problems with early literature on the demand for money; difficulties with autocorrelation arising from the presence of the lagged money stock which possessed a significant role. Thus, the distinction between the long-run and short-run demands for money surfaced. Chow (1966) argued that short-run money demand adjusted slowly toward long-run equilibrium; this stock-adjustment specification has weathered significant storms and remains the centerpiece of many money demand studies. The stock-adjustment specification did not go unchallenged, however.

Feige (1967) demonstrated that a model of the long-run demand for money produces equations similar to those emanating from the stock-adjustment model without requiring slow adjustment of money demand when the determinants of demand are permanent, rather than current, values. No distinction exists between long-run and short-run demands for money. The long-run money demand depends on permanent (long-run) values of the determinants of money demand. To the extent that permanent variables can be modeled with distributed lags of measured values, the inclusion of measured, rather than permanent, variables into money demand mimics the stock-adjustment specification. Second, the stock-adjustment model implies unusual dynamic adjustment when the money stock is exogenous. The determinants of money demand must overshoot their long-run (permanent) values to clear the money market on a period-by-period basis (Walters 1966) and (Starleaf 1970).

This demand for money specification has received renewed attention in the 1990s with econometric advances in the area of cointegration. A large body of literature has emerged that investigates long-run properties of the conventional money demand equation for various countries. Evidence with regard to a long run money demand relationship in the United States, particularly with M1 during the postwar period, is mixed. Miller (1991), Hafer and Jansen (1991), Friedman and Kuttner (1992), Stock and Watson (1993), and Norrbin and Reffett (1995a) as cited in Dutkowsky and Atesoglu (2001) find little support for cointegration for the conventional static money demand equation with M1.

Some studies, though, have produced more positive results, especially with adjustments in the basic specification. Hoffman and Rasche (1991) as cited in Dutkowsky and Atesoglu (2001) find evidence supporting cointegration with a dummy variable to reflect a shift in the deterministic trend in money demand during the 1980s. Baba, Hendry, and Starr (1992) as cited in Dutkowsky and Atesoglu (2001) provide support for a long-run relationship with an augmented model that includes risk, inflation, and a measure of the interest rate spread. Hoffman, Rasche, and Tieslau (1995) as cited in Dutkowsky and Atesoglu (2001) present perhaps the most supportive empirical findings. With a dummy variable included they obtain evidence of a stable long-run static money demand relationship for M1 in five industrial countries. A key to their results is the imposition of unitary long-run income elasticity. So far a deliberate gap seems to have occurred in the period between the after the 1960s and the 1990s as I skipped into the 1980s. The omission is deliberate; this is so as the next section delves into the work by Stephen M Goldfeld in the 1970s.

In 1973, Stephen M. Goldfeld examined the issues systematically, using quarterly postwar data up to 1973. Although Goldfeld's results differed in several important ways from those of the earlier literature, which were based mainly on annual data, his preferred specification became the standard formulation. The form of the Goldfeld equation is shown in below. The empirical estimates of the equation;

$$\ln(M_t/P_t) = \alpha_0 + \alpha_1 \ln GNP_t + \alpha_2 \ln RMS_t + \alpha_3 \ln RSAV_t + \alpha_4 \ln(M_{t-1}/P_{t-1})$$

Where,

M_t = currency plus checkable deposits;

P = the aggregate price level;

GNP = real gross national product;

RMS = a short-term market rate of interest;

$RSAV$ = rate of interest on savings deposits.

In summary, Goldfeld discovered that the quarterly demand function for money was most stable when:

- (i) A narrow transactions definition of money was used;
- (ii) A short-term market rate of interest like the Treasury bill or commercial paper rate was used and when the rate on savings deposits was included;
- (iii) Measured income (real GNP) was used rather than permanent income or wealth; and
- (iv) Lagged money was included to allow for incomplete adjustment in the short run.

One of the important stability tests that Goldfeld performed was to examine the ability of his equation to forecast outside the sample period. It showed no systematic tendency to drift off in such forecasts up to 1973, the year of his original study. Goldfeld (1973) thus discovered a single-equation econometric model expressing the demand for real M1 as a stable function of real GNP and nominal interest rates which did a remarkably good job of characterizing quarterly U.S. data during 1952-1972. This was confirmed both by the accuracy of its forecasts and by the inability of a Chow test to reject the hypothesis of parameter constancy across subsamples.

But starting in 1974, forecasts from this equation began to seriously over predict real money balances. These forecasts were out-of-sample dynamic simulations, which used actual interest rates and income but last period's predicted money balances as the lagged dependent variable. Three years later, again, Goldfeld (1976) found that by the same criteria of the accuracy of forecasts and the results of Chow tests, the performance of his money demand equation deteriorates markedly when the sample

period is extended to 1976. In fact, money demand regressions continue to be plagued by instability when the sample runs through the present day, with their forecasts systematically over predicting actual real M_1 figures for the late 1970s and under predicting actual figures for the 1980s.

These simulations showed a cumulative drift from the first quarter of 1974 to the second quarter of 1976 of nearly 9 percent. Moreover the error was almost entirely confined to the demand deposit component of M_1 , which had an error of over 13 percent. The monetary equations in the Federal Reserve Board's FMP Model gave similar results, this evidence of systematic over prediction of real money balances by the standard money demand function suggested that the demand for money had shifted down. This possibility was taken to mean that the demand for money had become "unstable" in the sense that it had become more difficult to predict *ex ante*.

Re-estimation of Goldfeld's specifications over the longer period confirmed that the failure was more pronounced in the business than in the household sector's equations. It is not surprising, therefore, that those institutional innovations, such as negotiable order of withdrawal (NOW) accounts, money market mutual funds, credit cards, savings deposits of business and state and local governments, and checking accounts at mutual savings banks, which have been credited with the instability were becoming more pronounced at thereabout the same time, Garcia, Gillian and Pak (1979).

However, a recurring debate that took place in Nigeria in the literature on the effectiveness of monetary policy to stabilize the Nigerian economy in terms of price stability and subsequently stimulating economic growth was on the nature and stability of the demand for money function. This debate started in the early 1970s amongst a group of scholars within the Lagos-Ibadan-Ife axis and was popularly called the 'TATOO' debate, an acronym coined from the initials of the major debaters of those days. The famous TATOO debate of the 1970s involved five different people; Tomori (1972), Ajayi (1976), Teriba (1974), Ojo (1974) and Odama (1974).

It was Tomori (1972) who first set out to examine the factors that influence the demand for money in the Nigerian economy, he tried to examine whether there was a stable or unstable demand for money function and examined what constituted a better definition of money in the Nigerian context. He adopted a very simple linear model expressing money as a function of nominal/real GDP. After applying the Ordinary Least Square (OLS) technique, he made the following conclusions.

- 1) Income is a significant variable explaining changes in money demand
- 2) Income is a more important variable determining money demand than interest rate.
- 3) The narrow definition of money seems to perform better than the broad
- 4) The coefficient of interest rate is not significant
- 5) Real income tends to show more significant relationship than nominal income.

Ojo (1974) questioned the work of Tomori especially his statistical methodology. He was concerned mainly with establishing that in a developing country like Nigeria, characterized by an underdeveloped money market, and lack of financial assets, the choice facing an individual is more between money and financial asset. He consequently specified and estimated (using the OLS technique) two kinds of relationship between money and its determinants. First, he specified real money balance as a function of current nominal income and interest rate. Second, following the insignificance of interest rates, he specified the real money balance as a function of nominal and expected rate of inflation.

According to Odama (1974), Tomori's model is devoid of any policy use in view of the fact that the only instrument (discount rate) turned out to be statistically insignificant. He also criticized Tomori in two aspects;

- 1) The formulation of an alternative model and the relevance of such a model for policy actions.
- 2) A modification of the statistical result and conclusion thereof.

Teriba (1974) observed that Tomori's paper suffered several methodological pitfalls and interpretational defects. According to him, treasury bills and time deposit are the closest substitutes for demand for currency and that adjustment lag between actual and desired cash balances is very close to zero, while income elasticity of demand for currency is greater than unity. On demand for money deposit, he said the closest substitute is time deposit while savings is also a better substitute than

treasury bills to demand deposit and the adjustment period is fairly fast while interest elasticity of demand for deposit is very low and income elasticity is also low.

Ajayi (1976) in addition to criticizing Tomori's paper (1972) provided answers to questions like, the stability of the demand function, adjustment mechanism and calculation of elasticity for policy decision making, using the narrow definition of money (M_1) he found out that income is about 80.5% responsible for variation in money demand but when he used M_2 , he found out that income even has more impact on money demand which was like 85%. When he introduced the rate of interest (on treasury bills), he got the wrong sign (positive) and the value was statistically insignificant. He attributed this to the underdeveloped nature of the country's money market. The interest elasticity of money was very low so also the adjusting mechanism but the income elasticity was high. In his conclusion he suggested the ineffectiveness of monetary policy in Nigeria.

As lively as the 'TATOO' debate was, the issue is still inconclusive. Two broad events seem to have dimmed the relevance of the debate carried out in those days. The first is the array of new estimation techniques (co-integration) and several test procedures available to researchers since the debate fettered in the early 1980s. The second is the development in the financial sector since the mid-1980s which may suggest some instability in the demand for money function in Nigeria. The first event has led to the re-examination of the nature and stability of the demand for money function using error correction methods (Teriba, 1992 and Nwaobi, 2004) as cited in Busari (2005)

Several studies have been carried out on the demand for money in Nigeria though not all made explicit attempts at investigating the stability of the money demand function as regards financial innovation. Asogu and Mordi (1987) as cited in Busari (2005) examine the monetary sector in general to uncover some of the main determinants of the money demand function. Ikhide and Fajingbesi (1998) as cited in Busari (2005) also examine whether deregulation of interest rate in Nigeria under the Structural Adjustment Programme (SAP) of 1986 has had any significant impact on the demand for money in Nigeria. Studies like Essen, Onwioduokit, and Osho (1996) as cited in Busari (2005) have dwelt extensively on issues relating to money demand in a liberalizing but heavily indebted economy using Nigeria as case study. The study observed that indebtedness could signal to private economic agents the direction of government fiscal and monetary policy which in turn influences the demand for money in the domestic economy. Audu (1988) as cited in Busari (2005) represents one of the first post-regulation era efforts to examine the stability of money demand function. Using selected West African countries, the study observed mixed results but was quick to observe a stable money demand relationship for Nigeria.

The study by Nwaobi (2002) as cited in Busari (2005), has also made efforts to examine the stability of the demand for money in Nigeria. Using a relatively simple model that specifies a vector valued autoregressive process (VAR), the money demand function was found to be stable and the author suggests that income is the an appropriate scale variable in the estimation of money demand function in Nigeria. In another study, Anoruo (2002) as cited in Busari (2005) explores the stability of the M_2 money demand function in Nigeria during the Structural Adjustment Program (SAP) period. In the study it was observed that the M_2 money demand function in Nigeria is stable for the study period. Further it was argued that M_2 is a viable monetary policy tool that could be used to stimulate economic activity in Nigeria.

3. Theoretical Framework and Model Specification

The conventional textbook formulation of the demand for money typically relates the demand for real money balances ($m = M/P$), to the interest rate, r , and some measure of economic activity such as real GNP ($y = Y/P$), where M = money holdings, P = the price level, and Y = gross national product. Thus,

$$m = f(r, y)$$

Several theories have been put forward to explain the equation above. Perhaps the most satisfying are those of the transactions view, in which the demand for money evolves from a lack of synchronization between receipts and payments and the existence of a transactions cost in exchanging money for interest-bearing assets (usually taken to be short term). (Goldfeld, 1973) Of relevance to this research project's model will be a select few. This will serve as a base for the model to be specified.

Keynes formulated his theory of demand in his well known book, the General Theory of Employment, Interest and Money in 1936. According to him, the demand for money arises out of its liquidity; liquidity refers to the convertibility of an asset into cash. He then identified three motives for holding money;

Transaction Motive: this arises out of money's medium of exchange role and arises out of the need for bridging the gap between periodic receipts and payments. Keynes recognized both the income motive for households and business motives for firms. Given the society's basic institutional and technical customs and practices which govern income receipt and the flow of expenditures, the transactions demand depends on personal income and business turnover. It thus varies in direct proportion to changes in money income. Symbolically it is written as:

$$L_t = k_t(Y)$$

Where;

L_t : Transactions demand for money

k_t : The fraction of money income society desires to hold as transaction balances.

Y : money income

Precautionary Motive: this arises out of unforeseen circumstances or expectations regarding the uncertain future by economic agents. Keynes posited that households sometimes keep money for unexpected contingencies such as medical emergencies or events while firms held balances above transactionary balances based on expectations about the economy e.g. a boom or depression. Keynes held that the level of precautionary balances varied with income and not interest rate changes. Symbolically;

$$L_p = k_p(Y)$$

Where;

L_p : Precautionary demand for money

k_p : The fraction of money income society desires to hold as precautionary balances.

Keynes usually lumped both motives together as they were both affected by the same institutional factors which he assumed given and fairly stable in the short run adding to the fact that they were both interest inelastic. Mathematically,

$$L_1 = L_t + L_p = k_t(Y) + k_p(Y) = k(Y)$$

Where;

L_1 : Demand for active balances

Speculative Motive: this falls under the idle balances held by economic agents according to Keynes. He posited that people hold or hoard money above their active balances for the purpose of being able to earn some form of gains by speculating on bond prices. Since individuals knew that an inverse relationship exists between bond prices and interest rate, they held money for the opportunity to partake in such speculative activities so as to earn some form of interest.

According to Keynes, there thus existed an inverse relationship between speculative demand for money and interest rates. Functionally, this is expressed as;

$$L_2 = f(i)$$

Where;

L_2 : Speculative demand for money

i : interest rate

Keynes concluded by positing that the total demand for money consists of demand for active balances (L_1) and that of idle balances (L_2). Thus,

$$L = L_1 + L_2$$

$$L = k(Y) + f(i)$$

However, Keynes demand for money theory has been criticized for unnecessarily bifurcating aggregate demand for money into transactions and speculative demand. The transactions demand for money depended on income level (but Keynes had assumed a constant relation between money holdings and income.) his speculative demand was based on portfolio approach which considered the yields of assets viz-a-viz their competition with money held in individuals' portfolio. Again, he further limited his analysis to two assets; money and bonds. The combination of demand motives with two different approaches is inconsistent (Paul, 2004).

Furthermore on the theory of the demand for money, Baumol-Tobin Portfolio Formulation of the Demand for Money is perhaps most widely taught demand for money theory which seeks to explain the demand for money as a function of income and interest rates. It arose as a defence by Keynesians to the inconsistencies of Keynes liquidity theory. Its simplest version is the so-called square root of money holdings and it was put forward by two economists. Tobin (February 1958), looked at the demand for money from the risk angle in his "Liquidity Preference as Behavior towards Risk" paper while Baumol (1952) in his "Transactions Demand For Cash: An inventory Theoretic Approach".

His equation is;

$$M = \left[\frac{kY}{2r} \right]^{1/2}$$

This implies that nominal money holdings for cost minimising individuals varies directly with the square root of planned nominal expenditures and inversely with the square root of market interest rate. It could also be expressed in real terms by deflating each nominal variable above with the price index.

Most empirical validations of the above theory use the narrow money stock (currency plus demand deposits, M1) as the dependent variable often deflated by the implicit GNP deflator. Income is defined as real GNP or GDP and the interest rate is usually measured in two ways; by the rate on commercial paper and by the rate on time deposits.

Several authors' regression specifications base their regressions using this style. E.g. (Hafer & Hein, 1984; Judd and Scadding, 1982) etc

Their explicit specification usually is:

$$M_t = \beta_0 + \beta_1 y_t + \beta_2 r_t^c + \beta_4 r_t^d + U_t$$

Where;

Y: income

r^c : Rate of commercial paper (variable used as a measure of financial innovation.)

r^d : Rate on time deposits.

M: monetary aggregate.

t: time

Usually the growth rate of Money supply is used; alternative specifications use a lagged value of Money supply as one of the regressors which necessitates the use of auto-correlation corrective techniques.

$$\ln M_t = \beta_0 + \beta_1 \ln y_t + \beta_2 \ln r_t^c + \beta_4 \ln r_t^d + \beta_5 \ln M_{t-1} + U_t$$

The resulting inference from their theory is that the demand for money is positively related to income and inversely related to interest rate.

3.1. Model Specification

To successfully examine the impact of financial innovation on the demand for money in Nigeria, the following model will be used for our empirical test.

$$M = f(Y, RTD, RTB, DSAP, CPI, M_{t-1}, u) \quad (i)$$

Where;

M: a monetary aggregate (in the case of this study M_2).¹

Y: Income as captured by Gross Domestic Product RGDP which seems to be most appropriate proxy variable for capturing the level of transaction².

RTD: Nominal Rate of interest on time deposits kept in commercial banks. Interest rate measures the opportunity cost of holding money that is, the reward for parting with liquidity. It reflects the degree of substitutability between money and bonds or other forms of financial assets. This is appropriate for our use of M_2 .

RTB: Nominal Rate on Treasury Bills³. (A Proxy variable for the 4-6 Month Commercial paper rate.)

DSAP: dummy variable to capture the financial innovations that have taken place since the sweeping reforms of the Structural Adjustment Programme (SAP) embarked upon by Nigeria in 1986 which led to changes in the financial system.⁴

CPI: Consumer Price level⁵

M_{t-1} : one period lag of M

t: Time period

u: Stochastic random term.

In a more explicit and econometric form;

$$M_t = \beta_0 + \beta_1 Y_t + \beta_2 RTD_t + \beta_3 RTB_t + \beta_4 DSAP + \beta_5 CPI + \beta_6 M_{t-1} + U_t \quad (ii)$$

Representing the above equation in a log-linear form;

$$\log M_t = \beta_0 + \beta_1 \log Y_t + \beta_2 \log RTD_t + \beta_3 \log RTB_t + \beta_4 DSAP + \beta_5 \log CPI + \beta_6 \log M_{t-1} + U_t \quad (iii)$$

A model of demand for money should establish a stable relationship between demand for money and the factors influencing it. Theoretically, the demand for money is hypothesized to be an increasing function of some measure of income or wealth. The coefficient of real income (β_1) should

¹ Miller (1991) finds that the natural logarithms of M_2 and Income (proxied by real GNP) are cointegrated. However Trehan (1984) as cited in Miller (1991) Found that in West Germany, real M_1 and M_2 were not cointegrated rather M_3 was more appropriate. However in Nigeria, as M_2 is more in line with official monetary conduct, it has been adopted as my monetary aggregate. Anoruo (2002) as cited in Busari (2005)

² Although, some authors contend that wealth is a better measure of capturing the level of transactions. E.g. Laidler (1993), Meltzer (1963) and Brunner and Meltzer (1963) as cited in Goldfeld (1973). There appears to be a common ground in literature that income could still be used.

³ The 4-6 month Commercial Paper rate is often used as an indicator for financial innovation, due to difficulty in accessing it I have decided to use a proxy as put forward by Goldfeld (1973:617) i.e. the Rate on treasury bills. Although some other authors such as Miller (1991) propose the use of the dividend- price ratio as a proxy, this is not readily available for the entire period under my scope.

⁴ Busari (2005) used a dummy variable to capture changes in the Nigerian financial sector since 1986 upwards. i.e post SAP.

⁵ Miller (1991) included price level in estimating the demand for money as he found it highly significant.

be positive since real income demanded rises with the level or value of transactions. The coefficients β_2 and β_3 of the two rates RTB and RTD respectively are expected to be negative. This is because of the inverse relationship that exists between interest rates and real cash balances.

The estimation technique to be used in the above model is the cointegration technique which is an improvement on the classical Ordinary Least Square (OLS) technique. One reason for the choice of this technique is that, first, it is generally argued that most economic series are non-stationary i.e. have a strong trend over time. By non-stationary, we mean that the variables do not have a mean which is constant over time and as such direct application of least squares technique could give spurious results. This causes the results of most OLS regressions to be statistically invalid and difficult to interpret in a theoretical context (Melnick, 1995).

Cointegration, error-correction modeling involves four steps. Though in a thin line separates steps two and three which necessitates their merging. First, determine the orders of integration for each of the variables under consideration; that is, difference each series successively until stationary series emerge. Second, estimate cointegration regressions with ordinary least squares, using variables with the same order of integration. Third, test for stationary residuals of the cointegration regressions. Finally, construct the error-correction models (Miller, 1991).

These steps are further explained as follows;

1) Determining the Order of Integration: The most popular approach is to use what are called augmented Dickey-Fuller, or ADF, tests. They were proposed originally by Dickey and Fuller (1979) under the assumption that the error terms follow an Autoregressive process of known order. Basically what this step seeks to do is establish whether a particular time series is stationary or non-stationary. If non-stationary then it has to be differenced either once or twice.

To carry out this test, we test the null hypothesis of a difference stationary against the alternative hypothesis of a trend stationary. That is:

$$H_0: Y_t \sim I(1)$$

$$H_1: Y_t \sim I(0)$$

The test statistics of the estimated coefficient of y_t is then used to test the null hypothesis that the series is non stationary. If the absolute value of the test statistics is higher than the absolute value of the critical T value (which could be at 1, 5 or 10 percent), then the series is said to be stationary, therefore, we reject the null hypothesis. If the null hypothesis cannot be rejected then y_t cannot be stationary i.e. y_t is non stationary. It may be of order one i.e. $I(1)$ or order two i.e. (2) or have an even higher order of integration. This will be revealed by differencing y_t till it becomes stationary.

2) Co integration Regression: The second stage proceeds to obtain the cointegration (error correction) vector in the regression equation using the Ordinary Least Square (OLS).

3) Test for stationary residuals of the co integration regressions: Here, we test if the residuals (u_t) are stationary. This involves examining the estimated residuals from the regression directly by performing a unit root test of the ADF type. Once it is discovered that the residuals here are stationary, then it is possible that our variables are cointegrated in the long run.

4) Construct the error-correction models (ECM): The final stage in the model building process requires the construction of error construction models. This involves regressing the first difference of each variable in the co integration equation onto lagged values of the first-differences of all of the variables plus the lagged value of the error-correction terms (that is, the error term from the co integration regression). (Miller, 1991) The ECM incorporates the full (short-run) dynamics of the stated model. At this stage, all the conventional statistical tests of significance are considered to be appropriate.

The purpose of the ECM is to switch to a short run model. The ECM indicates the speed of adjustment from short run equilibrium to the long run equilibrium state. The greater the co-efficient of the parameter, the higher the speed of adjustment of the model from the short run to the long run.

4. Data Analysis and Interpretation

This section presents the results obtained in the study. Table 4.1 shows the unit root test of the variables at levels while table 4.2 shows the unit root test of the variables at the first difference. Table 4.3 shows the unit root test of the residual obtained from the ordinary least square regression while table 4.4 shows the error correction model.

Table 4.1: Unit Root Test at Levels

VARIABLE	ADF (UNTRENDED)	ADF(TRENDED)
LOGM2	-0.830393	-2.504330
LOGRTD	-1.378753	-0.424075

DLOGRGDP	-3.678475*	-3.646344*

Note: * Stationary at 5 percent

** Stationary at 10 percent

4.1. Results Discussion

Here, a series stationarity tests was carried out on all variables. This test is paramount due to the non-stationarity feature of most annual time series data. This was carried out using the Augmented Dickey Fuller (ADF) test statistics. Table 4.1 above showed that all the variables were not stationary in levels. This can be seen by comparing the observed values (in absolute terms) of the ADF test statistics with the critical value (also in absolute terms) of the test statistics at the 5% and 10% level of significance test. Therefore, the null hypothesis is accepted and it is sufficient to conclude that there is the presence of unit root in the variables at the 5% and 10% levels of significance.

Following from the results obtained above, all the variables were differenced once the ADF test was conducted on them. Table 4.2 shows the results obtained. A close look at the table reveals that all variables are stationary at the 5% level of significance except M_2 , which was significant at the 10% level of significance. Also, CPI was not stationary when a trend was applied to it in its first difference form. Thus, on the basis of the results in table 4.2, the null hypothesis is rejected and it is safe to conclude that the variables are stationary. This implies that the variables are I (1) series, i.e. integrated of order 1.

4.1.2. Co-integration Test

Here, two steps take place here, firstly, an ordinary least squares regression was carried out using the variables in our model specified with the exclusion of DSAP. This thus converts the form of our model to:

$$\text{Log } M_t = \beta_0 + \beta_1 \log \frac{Y_t}{P_t} + \beta_2 \log RTD_t + \beta_3 \log RTB_t + \beta_5 \log CPI + \beta_6 \log M_{t-1} + U_t$$

Our results are thus presented in the appendix.

The residuals from the above regression are then saved and tested for stationarity (using the ADF method) to prove if the variables are cointegrated in the long run before an error correction model can be put forward. Given that the residuals from the co-integrating regression are stationary, then it is possible for cointegration to take place among our variables. The result of the unit root test of the residuals is presented in table 4.3 below;

Table 4.3: Unit Root Test of Residuals

VARIABLE	ADF TRENDED	ADF UNTRENDED
RESID	-4.971036	-4.845470

From the table above, the residual was stationary at 5% level of significance. As a result of this; one can rightly say that there is a long run relationship between all the variables used in the demand for money function. Given this result, it is now possible to proceed to estimate an error correction model, to reconcile the short-run behavior of the variables in the specified model with their long-run behavior. The critical ADF test statistic at levels for the residual is (-2.957110 and -2.617434) Untrended and (-3.557759 and -3.212361) trended for (5% and 10% respectively).

4.1.3. Error Correction Presentation

This is the last stage in the cointegration process and involves estimating our previous equation however this time with our error correction factor as a dependent variable. This involves regressing the first difference of each variable in the cointegration equation onto lagged values of the first-differences of all of the variables plus the lagged value of the error-correction term.

The result obtained is presented below;

Table 4.4: Short run Error Correction Model

VARIABLE	COEFFICIENT	STD. ERROR	T.STAT
C	0.118694	0.047476	2.500101
DLOGCPI	0.301801	0.080615	3.743719
DLOGRGDP(-3)	1.424761	0.316660	4.499345
DLOGRTD	0.114115	0.0773840	1.474653
DLOGRTD(-3)	-0.190934	0.086969	-2.195435
DLOGRTB	-0.044140	0.075042	-0.588204
DLOGM2(-1)	0.459597	0.187357	2.453051
DLOGM2(-3)	-0.280104	0.113231	-2.473728
DSAP	-0.034131	0.031105	-1.097300
EC(-1)	-0.601865	0.252520	-2.383429

R-SQUARED: 0.797900
 ADJUSTED R-SQUARED: 0.711285
 D-W STATISTIC: 2.190635
 F-STATISTIC: 9.212085

A close inspection of the table above indicates that the error correction model has a high coefficient of determination. This can be seen from R-squared of 79 percent and the adjusted R-squared of about 71 percent. The R-squared shows the percentage of variation in the dependent variable that was accounted for by variations in the explanatory variables. The F-statistic value of 10.84832 shows that the overall model is statistically significant at 1% and 5% levels of significance. This is because it is greater than the critical values of 2.57 and 3.79 at 1% and 5% respectively. This means that all the explanatory variables simultaneously explain the variations in the real demand for money. Also, all our variables are statistically significant at 95% confidence interval with the exception of DSAP, RTB and RTD. Furthermore, the DW statistic, which is a measure of auto correlation, shows that the error correction model is free from the problem of serial correlation due to its value (2.19). As a result of this, an error correction model estimated can be confidently relied upon for making inferences on role of financial innovation on the demand for money.

The EC, which is the error correcting term in the model, indicates the speed of adjustment from short run equilibrium to the long run equilibrium state. The greater the co-efficient of the parameter, the higher the speed of adjustment of the model from the short run to the long run. In the model, one would notice that the ECM (*EC* above) is statistically significant at 5%. This shows that there's a dynamic adjustment from short run to long run. The coefficient of the ECM is 0.60. This indicates that 60% of the errors in the short run are corrected in the long run.

As regards the behaviour of our explanatory variables with respect to the regressand, a positive relationship exists between the third lag of RGDP (to take care of exigencies) and M_2 confirming economic theory (Keynes et al) as regards the relationship between income and the demand for cash balances. Secondly, interest rate also conformed to our apriori expectation in that, the sign of its coefficient is negative implying an inverse relationship between the demand for cash balances and the rate of interest. The third variable in our model CPI also aligns with theory in that it has a positive sign.

The variable often used to capture financial innovation in most empirical literature is the 4-6 month commercial paper (being proxied by the treasury bill rate in our model) the co-efficient of it in our model is negative (-0.044140) which confirms what theory says. However, it is not statistically significant. It was not dropped as this affected our Akaike information criterion; raising its value. This could be traced to the poor development of the money market where the treasury bill rate rules. This thus leads to a conclusion that financial innovation has had an impact though not significant impact on the demand for money in Nigeria under the period of our scope. The innovations that have occurred given the massive financial sector reforms that characterized the SAP era have had an impact on the demand for money though this is not significant hence, our result tallies with that of Busari (2005). Worthy of note is that though at present an appreciable level of innovation seems to be taking place at present, it is post consolidation which is outside the scope of this research project.

H₀: SAP era financial sector liberalization policies have had no impact on the Demand for money.

H₁: SAP era financial sector liberalization policies have had an impact on the Demand for money.

In order to investigate whether the financial sector liberalization during SAP in the Nigerian economy has affected the real demand for money, a dummy variable was included in the error correction model. The dummy variable was not significant at the 5 percent level however its exclusion raised the value of our Akaike Information Criteria and affected the values of some of our regressors. In spite of this, its co-efficient took on a negative sign. This means that Structural Adjustment Programme which saw to sweeping changes in financial sector has not led to some financial innovations which indirectly or directly affect the demand for money.

5. Conclusions and Recommendations

This study has looked at the demand for money and how it has been affected by financial innovations in the financial sector of Nigeria arising out of the Structural Adjustment Programme (SAP) of 1986. The term financial innovation refers to anything which ensures greater access to information, quicker means of carrying out transactions and greater ease of liquidity with lower risk. It need not be a technological innovation as Solans (2003) pointed out even the 'euro' is a financial innovation, It has both reduced transaction costs and eliminated exchange rate risks, and has also acted as a catalyst for a number of improvements in various areas that have helped to create a more efficient financial system in the euro area as a whole. However, its effect on the demand for money is what has aroused so much interest to it among economic scholars. Of particular interest has been its effect on the stability of the demand for money, in that if its impact on the demand for money is significantly large, then the effectiveness of monetary policy may be seriously threatened. In order to ascertain this impact, a model was specified and estimated using the cointegration technique method. Data for the analysis was taken from 1970-2008.

5.1. Main Findings and their Implications

After carrying out appropriate analysis using our model, it was discovered that on the basis of individual tests of significance, all the slope coefficients were individually statistically significantly different from zero with the exception of DSAP, RTD and RTB which failed the test of significance at the 5% level. Hence our major findings are as follows;

- 1) Lagged Interest on time deposits is negatively related to the demand for money.
- 2) Lagged Treasury bill rate is negatively related to the demand for money.
- 3) Real income is positively related to the demand for money.
- 4) Price level is positively related to the demand for money.
- 5) Structural Adjustment Programme has had an indirect effect on the demand for money via financial innovation.

In view of the above findings, the following are possible implications arising;

- 1) The low interest elasticity of our demand for money is indicative of underdeveloped nature of the money market in Nigeria. The money market particularly the treasury bills are dominated by government (the Central Bank) with the end result being that the market lacks the depth and flexibility that it might have had with the presence of a diversified participant base. This is also indicative of the ill developed nature of our financial system. Keynesian doctrine holds that for the smooth functioning of his liquidity preference theory the money market must be well developed.
- 2) Income level is a primary determinant of demand for money by economic agents in Nigeria.
- 3) The analysis also shows that for the atmosphere to be conducive for the effective use of monetary policies, financial innovations should be made to affect the demand for money significantly; there is still a place for monetary policy as a macroeconomic stabilization measure.

5.2. Recommendations

In view of the above findings, this study has shown that financial sector liberalization which was one of the goals of SAP has not led to financial innovation which would have benefitted banking customers, deepened the money market and affected the effectiveness of monetary policy. It has also not had a significant impact on the demand for money. In the light of these findings, this research project suggests the following recommendations;

- 1) A policy of attracting more participants (non-government) and private sector funds to the money market is necessary as this will deepen the market and make the market more dynamic

and amenable to monetary policy. This will further reduce the present long time lags associated with monetary policy in Nigeria.

- 2) Although, from our results financial innovation have not affected the demand for money thus there is still a basis for monetary policy. Moreso, in the light of the recent recapitalization in the Nigerian banking sector which have led to financial innovations, the monetary policy strategy of the CBN should be fine-tuned to ensure it is well suited to deal with the challenges posed by financial innovation. The bank needs to be anticipatory through proper monitoring of the financial landscape, by following developments closely and by trying to predict the consequences of financial innovations that, at first, may appear very marginal.

5.3. Conclusion

In conclusion, financial innovations can help to increase the efficiency of the financial system, but at the same time they complicate the environment in which monetary policy operates by affecting the demand for money function making it unstable. But no matter how unstable the demand for money function is, the Central Bank of Nigeria through the commercial banks should make funds available via lending of loans so as to aid industrial growth, by reducing the lending (interest) rate.
