Determination of susceptibility of causal agents of bacterial conjunctivitis to antibiotics: Federal Medical Center, Imo State, Nigeria as Case Study

C.L. Eze, W. Braide, S.U. Oranusi and E.E. Mike-Anosike

Introduction
Bacterial conjunctivitis which occurs in patients of all ages is characterized by itching of the eyelid, grittiness on waking, infection of the lash follicle and redness of the eye (Tarabishy and Jeng, 2008). The infection is highly contagious, being easily transmitted by contaminated fingers, towels and handkerchief and contact with infected genital discharges (Baron, 1990; Willey et al., 2008; Duguid et al., 1980). The spectrum of organisms causing conjunctival disease varies around the world. Morrow and Abbot (1998) and Olatunji (2004) reported that Staphylococcus aureus, Streptococcus pneumoniae and Haemophilus sp are common causes of non-gonococcal bacterial conjunctivitis. The proportion of viral and allergic conjunctivitis has largely increased in recent years, but the share of bacterial conjunctivitis in the ophthalmological incidence still remain high, about 33% (Fox et al., 1995). In a neonatal intensive care unit, the most common organisms isolated in patients with conjunctivitis were coagulase-negative staphylococci, S. aureus, Neisseria gonorrhoea and Klebsiella sp (Olatunji, 2004; Willey et al., 2008). Iwolakun et al. (2011) and Brook (2008) reported mixed cultures of Pseudomonas,
Corynebacterium sp, Klebsiella, Enterobacter aerogenes, Escherichia coli, S. aureus, Moraxella sp, coagulase negative staphylococci and Chlamydia trachomatis.

The bacteriological and plasmid analysis of some causal agents of conjunctivitis has been investigated by Iwalokun et al. (2011). Willey et al. (2008) and Baron (1990) had reported on the increasing multiple antibiotic resistance of Staphylococcus aureus and Neisseria gonorrhoea. A healthy conjunctiva is necessary for the maintenance of a healthy and functional cornea. Infection of conjunctivitis and related ophthalmological diseases may spread to the cornea and results in keratoconjunctivitis, inclusion conjunctivitis and ulcer because of close proximity to the conjunctiva (Willey et al., 2008). This paper reports on bacterial conjunctivitis and their response to some antibiotics among patients in the eye care unit of the Federal Medical Centre, Owerri, Imo State, Nigeria.

Materials and Methods

Collection of specimen
The tip of sterile swab sticks moistened with sterile physiological saline (0.9% NaCl) was used to collect profuse discharges from 60 (4 neonates, 21 adult female and 35 adult males) confirmed conjunctival patients that visited the Federal Medical Centre, Owerri, Imo State. Specimens were collected by gently rubbing the swabs along the lower fornix of the conjunctiva.

Inoculation of specimen
Swabs loaded with the specimen was gently streaked onto freshly prepared surface dried media (blood agar, chocolate agar, nutrient and MacConkey agar) and incubated at 37°C for 48h (Ogbulie and Ojiakor, 2003; Cheesbrough, 2000).

Identification if bacterial isolates
Pure cultures were screened on the basis of colonial, microscopic and biochemical characteristics of the isolates (Beishir, 1987, Cheesbrough, 2000) and the identities confirmed with reference to standard manuals (Buchanan and Gibbons, 2000).

Antibiotics screening
Disc agar diffusion method described by Kirby-Bauer was adopted to determine antibiotic sensitivity test (Duguid et al., 1980). Twenty four old broth cultures of the identified bacteria were standardized (McFarland 0.5) and moistened with a sterile swab stick, and then gently streaked on the surface of freshly prepared Mueller Hinton agar, and allowed to stand for 30 minutes on the bench. Commercial antibiotic disc (Oxoid) of different concentrations was firmly placed equidistant from each other on the outer portion of the culture plate. Plates with the disc were allowed to stand for 3h and later incubated for 24-48h at 37°C. Zones of inhibition measured in diameter were recorded after incubation.

Results
Colonial morphology and microscopic and biochemical characteristics of the bacterial isolates are shown in Tables 1 and 2 respectively. The predominant bacterial isolates include; Staphylococcus aureus (28.12%); Streptococcus pneumoniae (23.08%); Haemophilus aegyptius (19.23%). Neisseria gonorrhoea, Corynebacterium and Escherichia coli were also isolated, representing 8.97%, 12.82% and 7.69% respectively (Table 3).

Staphylococcus aureus was sensitive to gentamycin, streptomycin and cotrimoxazole but showed high resistance to nitrofurantoin, colistin sulphate, ampicillin, nalidixic acid and tetracycline. Streptococcus spp was sensitive to nalidixic acid, streptomycin and nitrofurantoin but resistance to colistin sulphate, tetracycline and cotrimoxazole. Neisseria gonorrhoea and Corynebacterium species were sensitive to ampicillin and tetracycline. All the bacteria isolated from the infected patients were resistant to chloramphenicol (Table 4).

The enterobacteriaceae species generally showed resistance to ceporex and zinnate. Gentamycin was sensitive against 52.6% of all the isolates, whereas streptomycin was effective against over 57.7% of the species of the six genera isolated. Zinnate was sensitive against 56.4% of the isolates while nitrofurantoin was effective against 38.5% of the isolates. Cotrimoxazole was effective against 53.9% of the isolates (Table 4).

Discussion

The spectra of bacteria isolated from conjunctival swabs were similar to the reports of others (Friedlaender, 1995; Merianos, 1995; Baron, 1990; Duguid et al., 1980; Willey et al., 2008). Staphylococcus aureus, Haemophilus aegyptus and Streptococcus pneumoniae were the most predominant. Neisseria gonorrhoea, Escherichia coli and Corynebacterium species were also isolated.

A proportion of the bacterial isolates were resistant to some commonly used antibiotics. Staphylococcus aureus for instance recorded 100% resistance to nitrofurantoin, ceporex, ampicillin, nitidixic acid, tetracycline and cotrimoxazole. This corroborate with the findings of Bravenly and Milatovic (1987) and Baron (1990). Streptococcus pneumoniae, one of the most frequent isolates was 100% resistance to chloramphenicol, tetracycline and cotrimoxazole. High resistance of Streptococcus pneumoniae to ampicillin (94.44%) and gentamycin (89%) had been reported by Morrow and Abbot (1998).

Some of the isolates, notably, Escherichia coli and Staphylococcus aureus may result from contamination or as commensals from the face and skin of many carriers with depressed immunity (Jone et al., 1990).

Neisseria gonorrhoea isolated from the eyes of neonates is sexually transmitted and highly contagious pathogens (Willey et al., 2008). Gonococcal ophthalmia also known as ophthalmia neonatorum is a disease condition in newborns infants transmitted through the birth canal of an infected mother (Willey et al., 2008; Duguid et al., 1980). Haemophilus aegyptius also known as “Koch-Weeks bacilli” is a commensal of the upper respiratory tract and is frequently isolated during epidemic involving camps and school environment (Baron, 1990). Corynebacterium species, though a part of the normal flora of the eye may become pathogenic when the immune system is compromised. Production of toxins contributes to the virulence of Corynebacterium species (Baron, 1990).

Greenhead et al. (2003) reported that penetrating injuries of the eyes and ophthalmic surgery may introduce a wide range of bacteria and fungi into the chambers of the eye which may give rise to hypopyon (pus in the eye). Choroidoretinitis, an infection of the back of the eye are seen in many diverse infectious diseases associated with immunocompromised individuals (Greenwood et al., 2003; Willey et al., 2008).

The high resistance of the bacteria to some narrow and broad spectrum antibiotics is worrisome giving the fact that the eye is usually exposed and susceptible to infections from dust and contaminated skin surfaces. Uncontrolled prescription of antibiotics by health workers and their indiscriminate use may account for the drug resistance resulting from mutant strains.
With the pattern of resistance to some of the antibiotics under investigations, the habit of drug abuse for the blind treatment of the infections, especially for the diseases of the eyes should be discouraged while the use of new and more effective antibiotics should be recommended. Basifloxacin a broad spectrum fluoroquinolone has been reported as a novel anti-infective agent in the treatment of bacterial conjunctivitis (Paterno et al., 2009; Comstock et al., 2009; McDonald et al., 2009; Haas et al., 2009; Comstock et al., 2010).
